

When many insects attack a tree at the same time, a barrier zone may develop around the entire tree. All the wood present at the time of wounding will be slightly altered. When dried, the wood present at the time of wounding will be a different shade from the wood that formed after wounding.

The cambium miner is a small larva of a type of fly that eats its way down the cambial region of some trees. The "tracks" of the larvae are compartmentalized as very long narrow streaks of discolored wood within growth rings.
