Local forest structure variability increases resilience to wildfire in dry western U.S. coniferous forests

Michael J. Koontz, Malcolm P. North, Chhaya M. Werner, Stephen E. Fick, and Andrew M. Latimer

INTRODUCTION

Forests are essential components of the biosphere, and ensuring their persistence is of high management priority given their large carbon stores and other valued ecosystem services (Trumbore et al. 2015; Higuera et al. 2019). Modern forests are subject to disturbances that are increasingly frequent, intense and entangled with human society, which may compromise their resilience and their ability to persist (Millar & Stephenson 2015; Seidl et al. 2016; Schoennagel et al. 2017; Hessburg et al. 2019; McWethy et al. 2019). A resilient forest can absorb disturbances and may reorganise, but is unlikely to transition to an alternate vegetation type in the long run (Holmgren 1973; Walker et al. 2004). Resilience can arise when interactions among heterogeneous elements within a system create stabilising negative feedbacks, or interrupt positive feedbacks that would otherwise cause critical transitions (Peters et al. 2004; Reyer et al. 2015a). System resilience can be generated by heterogeneity at a variety of organisational scales, including genetic diversity (Reusch et al. 2005), species diversity (Chesson 2000), functional diversity (Gazol & Camarero 2016), topoclimatic complexity (Lenoir et al. 2013) and temporal environmental variation (Questad & Foster 2008). Forest resilience mechanisms are fundamentally difficult to quantify because forests comprise long-lived species, span large geographical extents, and are affected by disturbances at a broad range of spatial scales (Reyer et al. 2015a, 2015b). It is therefore critical, but challenging, to understand the system-wide mechanisms underlying forest resilience and the extent to which humans have the capacity to influence them.

Wildfire severity describes a fire’s effect on vegetation (Keeley 2009) and high-severity fire, in which all or nearly all overstorey vegetation is killed, can be a precursor to state transitions in dry coniferous forests (Stevens et al. 2017; Davis et al. 2019). For several centuries prior to Euroamerican invasion, fire regimes in this ecosystem were variable as a consequence of both natural and indigenous burning, with primarily low- and moderate-severity fire and localised patches of high-severity fire (Safford & Stevens 2017). Most dry coniferous tree species in frequent-fire forests did not evolve mechanisms to protect propagules (e.g. seeds, buds/stems that can resprout) from high-severity fire, so recruitment in large patches with few or no surviving trees is often limited by longer-distance dispersal of tree seeds from unburned or lower-severity areas (Welch et al. 2016; Stevens-Rumann & Morgan 2019). In the Sierra Nevada, the absence of tree seeds after severe wildfire can lead to forest regeneration failure as resprouting shrubs outcompete slower-growing conifer seedlings and provide continuous cover of flammable fuel that makes future high-severity wildfire more likely (Collins & Roller 2013; Coppolletta et al. 2016), though this pathway does not materialise in forests with a slower post-fire vegetation response (Prichard & Kennedy 2014; Stevens-Rumann et al. 2016). Dry forest regeneration is especially imperilled after high-severity fire when post-fire climate conditions are suboptimal for conifer seedling

Abstract

A ‘resilient’ forest endures disturbance and is likely to persist. Resilience to wildfire may arise from feedback between fire behaviour and forest structure in dry forest systems. Frequent fire creates fine-scale variability in forest structure, which may then interrupt fuel continuity and prevent future fires from killing overstorey trees. Testing the generality and scale of this phenomenon is challenging for vast, long-lived forest ecosystems. We quantify forest structural variability and fire severity across >30 years and >1000 wildfires in California’s Sierra Nevada. We find that greater variability in forest structure increases resilience by reducing rates of fire-induced tree mortality and that the scale of this effect is local, manifesting at the smallest spatial extent of forest structure tested (90 × 90 m). Resilience of these forests is likely compromised by structural homogenisation from a century of fire suppression, but could be restored with management that increases forest structural variability.

establishment (Davis et al. 2019) or optimal for shrub regeneration (Young et al. 2019).

Many dry western U.S. forests are experiencing ‘unhealthy’ conditions which leave them prone to catastrophic shifts in ecosystem type (Millar & Stephenson 2015; McWethy et al. 2019). First, a century of fire suppression has drastically increased forest density and fuel connectivity (Safford & Stevens 2017), which increases competition for water (D’Amato et al. 2013; van Mantgem et al. 2016) and favours modern wildfires with larger, contiguous patches of tree mortality whose interiors are far from potential seed sources (Miller & Thode 2007; Safford & Stevens 2017; Stevens et al. 2017; Steel et al. 2018). Second, warmer temperatures coupled with recurrent drought exacerbate water stress on trees (Williams et al. 2013; Millar & Stephenson 2015; Clark et al. 2016), producing conditions favourable for high-intensity fire (Fried et al. 2004; Abatzoglou & Williams 2016) and less suitable for post-fire conifer establishment (Stevens-Rumann et al. 2018; Davis et al. 2019). Thus, the presence of stabilising feedbacks that limit high-severity fire may represent a fundamental resilience mechanism of dry coniferous forests, but anthropogenic climate and management impacts may be upsetting those feedbacks and eroding forest resilience.

Resilience to disturbances such as wildfire may derive from heterogeneity in vegetation structure (Turner & Romme 1994; Stephens et al. 2008; North et al. 2009; Virah-Sawmy et al. 2009). Forest structure – the size and spatial distribution of vegetation in a forest – links past and future fire disturbance via feedbacks with fire behaviour (Agee 1996). A structurally variable forest with horizontally and vertically discontinuous fuel may experience slower-moving surface fires, a lower probability of crown fire initiation and spread, and a reduced potential for self-propagating, eruptive behaviour (Scott & Reinhardt 2001; Graham et al. 2004; Peters et al. 2004; Fox & Whitesides 2015; Parsons et al. 2017). Feeding back to influence forest structure, this milder fire behaviour, characteristic of pre-Euroamerican settlement conditions in dry western U.S. forests, generates a heterogeneous patchwork of fire effects including consumed understorey vegetation, occasional overstorey tree mortality and highly variable structure at a fine scale (Sugihara et al. 2006; Scholl & Taylor 2010; Cansler & McKenzie 2014; Safford & Stevens 2017). Thus, more structurally variable dry forests are often considered more resilient and are predicted to persist in the face of frequent wildfire disturbance (Graham et al. 2004; Moritz et al. 2005; Stephens et al. 2008).

While the homogenizing effect of modern high-severity fire on forest structure is well-documented (Steel et al. 2018), the foundational concept of feedback between heterogeneity of forest structure and fire severity is underexplored at the ecosystem scale, in part because of the dual challenges of measuring fine-grain vegetation heterogeneity at broad spatial extents (Kane et al. 2015; Graham et al. 2019) and linking local, bottom-up processes to emergent ecosystem-wide patterns in an empirical setting (Turner & Romme 1994; Bessie & Johnson 1995; McKenzie & Kennedy 2011, 2012). Furthermore, it has been difficult to resolve the ‘scale of effect’ (Graham et al. 2019) for how variability in forest structure is meaningful for resilience (Kotliar & Wiens 1990; Turner et al. 2013).

Advances in the accessibility and tractability of spatiotemporally extensive Earth observation data (Gorelick et al. 2017) provide an avenue to insight into fundamental ecosystem properties at relevant scales, such as resilience mechanisms of vast, long-lived forests. We use Landsat satellite imagery and a massively parallel image processing approach to calculate wildfire severity for over 1000 Sierra Nevada yellow pine/mixed-conifer wildfires encompassing a wide size range (4 to >100 000 hectares) and long time series (1984–2018). We calibrate these spectral severity measures to ground assessments of fire effects on overstorey trees from 208 field plots. For each point within these c. 1000 fires, we use texture analysis (Haralick et al. 1973) at multiple scales to characterise local variability in vegetation structure across broad spatial extents and determine its ‘scale of effect’ (Graham et al. 2019). We pair the resulting extensive database of wildfire severity and multiple scales of local forest variability to ask: (1) Does spatial variability in forest structure increase the resilience of California yellow pine/mixed-conifer forests by reducing the severity of wildfires? (2) What is the ‘scale of effect’ of structural variability that influences wildfire severity? and (3) Does the influence of structural variability on fire severity depend on topography, regional climate or other conditions?

MATERIAL AND METHODS

Study system

Our study assesses the effect of vegetation structure on wildfire severity in the Sierra Nevada mountain range of California in yellow pine/mixed-conifer forests (Fig. 1; Supporting Information methods). This system is dominated by a mixture of conifer species including ponderosa pine (Pinus ponderosa Lawson & C. Lawson), sugar pine (Pinus lambertiana Douglas), incense-cedar (Calocedrus decurrens (Torr.) Florin), Douglas-fir (Pseudotsuga menziesii (Mirb.) Franco), white fir (Abies concolor (Gord. & Glend.) Lindl. ex Hildebr.), and red fir (Abies magnifica A. Murray bis), angiosperm trees primarily including black oak (Quercus kelloggii Newberry), as well as shrubs (Ceanothus spp., Arctostaphylos spp.) (Safford & Stevens 2017).

Programmatically assessing wildfire severity

We measured forest vegetation characteristics and wildfire severity using imagery from the Landsat series of satellites post-processed to surface reflectance using radiometric corrections (Masek et al. 2006; Vermote et al. 2016; USGS 2018a,b). Landsat satellites image the entire Earth approximately every 16 days with a 30 m pixel resolution. We used Google Earth Engine for image collation and processing (Gorelick et al. 2017).

We calculated wildfire severity for the most comprehensive record of fire perimeters in California: the Fire and Resource Assessment Program (FRAP) fire perimeter database (https://frap.fire.ca.gov/frap-projects/fire-perimeters/). The FRAP database includes all known fires that covered more than 4 hectares, compared to the regional standard database which...
includes fires covering greater than 80 hectares (Miller & Safford 2012; Steel et al. 2018) and the national standard database Monitoring Trends in Burn Severity (MTBS) which includes fires covering greater than 400 hectares in the western U.S. (Eidenshink et al. 2007). Smaller fire events are important contributors to fire regimes, but their effects are often underrepresented in analyses of fire effects (Randerson et al. 2012). The FRAP perimeters are error-checked, but it is possible that duplicated events are occasionally represented in the database. Using the FRAP database, we quantified fire severity within each perimeter of 1008 wildfires in the Sierra Nevada yellow pine/mixed-conifer forest that burned between 1984 and 2018, which more than doubles the number of fire events with severity assessments compared to the regional standard database.

We created per-pixel median composites of collections of pre- and post-fire images for each fire to calculate common spectral indices of wildfire severity. Pre-fire image collections spanned a fixed time window ending the day before each fire’s discovery date and post-fire image collections spanned the same fixed time window, exactly one year after the pre-fire window. We tested four different time periods (16, 32, 48, and 64 days) that defined the time window of the pre- and post-fire image collections, and seven common spectral indices of severity (RBR, dNBR, RdNBR, dNBR2, RdNBR2, dNDVI, RdNDVI) for a total of 28 different means to remotely measure wildfire severity (Supporting Information methods).

We calibrated these 28 severity metrics with 208 field assessments of fire effects from previous studies (Zhu et al. 2006; Sikkink et al. 2013). Severity was measured in the field as the overstorey component of the Composite Burn Index (CBI) – a metric of vegetation mortality across several vertical vegetation strata within a 30m diameter field plot. The overstorey component of CBI characterises fire effects to the overstorey vegetation specifically, which includes both dominant/co-dominant big trees as well as intermediate-sized subcanopy trees (generally 10–25 cm DBH and 8–20 m tall) (Key & Benson 2006). CBI ranges from 0 (no fire impacts) to 3 (very high fire impacts), and is a common standard for calibrating remotely-sensed severity data in western U.S. forests (Key & Benson 2006; Miller & Thode 2007; Miller et al. 2009; Cansler & McKenzie 2012; Parks et al. 2014, 2018; Prichard & Kennedy 2014). We extracted each spectral severity metric at the CBI plot locations using both bilinear and bicubic interpolation (Cansler & McKenzie 2012; Parks et al. 2014, 2018) and fit a non-linear model:

\[
\text{remote\_severity} = \beta_0 + \beta_1 e^{b_{\text{cbi\_overstorey}}}
\]  

We treated the spectral severity measure as the dependent variable in this nonlinear regression for comparison with other studies (Miller & Thode 2007; Miller et al. 2009; Parks et al. 2014). We performed tenfold cross validation using the modelr and purrr packages (Henry & Wickham 2019; Wickham 2019) and report the average \( R^2 \) value for each model. We used the severity calculation derived from the best fitting model for all further analyses (Relative Burn Ratio [RBR] calculated using a 48-day time window; tenfold cross validation \( R^2 = 0.806 \); first panel of Fig. 2; Table S1).

Using the non-linear relationship between RBR and CBI, we calculated the threshold RBR corresponding to ‘high-severity’ signifying complete or near-complete overstorey mortality using the common CBI high-severity lower threshold of 2.25 (i.e. an RBR value of 282.335; Fig. 3) (Miller & Thode 2007).
Assessing local forest structure variability at broad extents

We used texture analysis to calculate a remotely-sensed measure of local forest variability (Haralick et al. 1973; Tuanmu & Jetz 2015).

Within a moving square neighbourhood window with sides of 90 m (3 × 3 pixels), 150 m (5 × 5 pixels), 210 m (7 × 7 pixels) and 270 m (9 × 9 pixels), we calculated forest variability for each pixel as the standard deviation of the NDVI values of its neighbours (not including itself). NDVI correlates well with foliar biomass, leaf area index, and vegetation cover (Rouse et al. 1973), so a higher standard deviation of NDVI within a given local neighbourhood corresponds to discontinuous canopy cover and abrupt vegetation edges (see Fig. 4) (Franklin et al. 1986).

Assessing other conditions

Elevation data were sourced from a 1-arc second digital elevation model (DEM) (Farr et al. 2007) which was used to calculate slope, aspect, and potential annual heat load—an integrated measure of latitude, slope, and aspect (McCune & Keon 2002; Supporting Information methods). Per-pixel topographic roughness was calculated as the standard deviation of elevation values within the same-sized kernels as those used for variability in forest structure (90 m, 150 m, 210 m, and 270 m on a side and not including the central pixel). We chose this specific measure of topographic roughness because it directly parallels and accounts for our metric of forest structure variability and because of its use in other studies (Holden et al. 2009), though other measures of topographic heterogeneity have been used for fire modelling (Haire & McGarigal 2009; Holden et al. 2009; Cansler & McKenzie 2014).

We calculated pre-fire fuel moisture as the median 100-h fuel moisture for the 3 days prior to the fire using gridMET, a gridded meteorological product with a daily temporal resolution and a 4 × 4 km spatial resolution (Abatzoglou 2013). The 100-hour fuel moisture is a correlate of the regional temperature and moisture which integrates the relative humidity, the length of day, and the amount of precipitation in the previous 24 h. Thus, this measure is sensitive to multiple hot dry days across the 4 × 4 km spatial extent of each grid cell, but not to diurnal variation in relative humidity nor to extreme weather events during a fire.

Modelling

Approximately 100 random points were selected within each FRAP fire perimeter in areas designated as yellow pine/mixed-conifer forest and we extracted the values of severity and covariate at those points using nearest neighbour interpolation. Using the calibration equation described in eqn 1 for the best configuration of the remote severity metric, we removed sampled points corresponding to ‘unburned’ area prior to analysis.
(i.e. below an RBR threshold of 45.097). The random sampling amounted to 56088 total samples across 1008 fires.

We used a hierarchical logistic regression model (eqn. 2) to assess the probability of high-severity wildfire as a linear combination of the remote metrics described above: pre-fire NDVI of each pixel, standard deviation of NDVI within a neighbourhood (i.e. forest structural variability), the mean NDVI within a neighbourhood, 100-hour fuel moisture, potential annual heat load, and topographic roughness. We included two-way interactions between the structural variability measure and pre-fire NDVI, neighbourhood mean NDVI, and 100-hour fuel moisture. We include the two-way interaction between a pixel’s pre-fire NDVI and its neighbourhood mean NDVI to account for structural variability that may arise from contrasts between these variables (e.g. ‘holes in the forest’ vs. ‘isolated patches’; Fig. S2). We scaled all predictor variables, used weakly-regularizing priors, and estimated an intercept for each individual fire with pooled variance (i.e. a group-level effect of fire). We used the \textit{brms} package to fit models in a Bayesian framework which implements the No U-Turn Sampler extension to the Hamiltonian Monte Carlo algorithm (Hoffman & Gelman 2014; Bürkner 2017). We used four chains with 5000 samples per chain (including 2500 warmup samples) and chain convergence was assessed for each estimated parameter by ensuring Rhat values were less than or equal to 1.01 (Bürkner 2017).

Figure 3 Example algorithm outputs for the Hamm Fire of 1987 (top half) and the American Fire of 2013 (bottom half) showing: pre-fire true colour composite image (left third), post-fire true colour composite image (centre third), relative burn ratio (RBR) calculation using a 48-day image collation window before the fire and one year later (right third). For visualisation purposes, the continuous severity index has been binned into severity categories.

Figure 4 Example of homogenous forest (top row) and heterogeneous forest (bottom row) with the same mean NDVI values (c. 0.6). Each column represents forest structural variability measured using a different neighbourhood size. NDVI is represented by a white to green colour gradient, and pixels that are not included in the forest structural variability metric are coloured grey.

Scale of effect of forest structure variability

Each neighbourhood size (90, 150, 210, 270 m) was substituted in turn for the neighbourhood standard deviation of NDVI, mean NDVI of the central pixel, and terrain roughness covariates to generate a candidate set of four models. To assess the scale at which these vegetation-size-dependent effects manifested, we compared the four candidate models using leave-one-out cross validation (Vehtari et al. 2017). We inferred that the neighbourhood size window used in the best-performing model reflected the scale at which the forest structure variability effect had the most support (Graham et al. 2019). We used R for all statistical analyses (R Core Team 2018).

RESULTS

Our programmatic assessment of wildfire severity calibrates as well or better than other reported methods that often require substantial manual intervention (Edwards et al. 2018). We found that this approach was robust to a wide range of spectral severity metrics, time windows, and interpolation techniques, including those based on NDVI, which are seldom used in this system (Fig. 2; Table S1; Supporting Information methods).

The model with the best out-of-sample prediction accuracy assessed by leave-one-out cross validation was the model fit using the smallest neighbourhood size for the variability of forest structure (standard deviation of neighbourhood NDVI), the mean of neighbourhood NDVI, and the terrain roughness (standard deviation of elevation) (Table 1). One hundred percent of the model weight belongs to the model using the smallest neighbourhood size window.

We report the results from fitting the model described in eqn 2 using the smallest neighbourhood size (90 × 90 m) because this was the best performing model (see above) and because the size and magnitude of estimated coefficients were similar across neighbourhood sizes (Table S2).

The strongest influence on the probability of a forested area burning at high-severity was the a pixel’s pre-fire NDVI, with a greater pre-fire NDVI increasing the probability of high-severity fire (βpre-fire_NDVI = 1.06; 95% CI: [0.931, 1.192]; Fig. 5). There was a strong negative relationship between 100-h fuel moisture and wildfire severity such that increasing 100-h fuel moisture was associated with a decreasing probability of a high-severity wildfire (βfm100 = −0.576; 95% CI: [−0.709, −0.442]) (Fig. 5). Potential annual heat load, which integrates aspect, slope, and latitude, also had a strong positive relationship with the probability of a high-severity fire. Areas that were located on southwest facing sloped terrain at lower latitudes had the highest potential annual heat load, and were more likely to burn at high-severity (βpahl = 0.246; 95% CI: [0.215, 0.277]) (Fig. 5). We found a negative effect of the pre-fire mean NDVI of the central pixel burning at high-severity (βnbhd_mean_NDVI = −0.168; 95% CI: [−0.311, −0.028]). This is in contrast to the positive effect of the pre-fire NDVI of the pixel itself. We found no effect of local topographic roughness on wildfire severity (βtopographic_roughness = 0.002; 95% CI: [−0.029, 0.034]).

There was also a strong negative interaction between the pre-fire NDVI of the central pixel (βnbhd_mean_NDVI*pre-fire_NDVI = −0.54; 95% CI: [−0.587, −0.494]).

From the same model, we found strong evidence for a negative effect of variability of vegetation structure on the probability of a high-severity wildfire (βnbhd_stdev_NDVI = −0.213; 95% CI: [−0.251, −0.174]); (Fig. 5). We also found significant interactions between variability of vegetation structure and pre-fire NDVI of the central pixel (βnbhd_stdev_NDVI*pre-fire_NDVI = 0.128; 95% CI: [0.031, 0.221]) as well as between variability of vegetation structure and pre-fire NDVI (βnbhd_stdev_NDVI*nbhd_mean_NDVI = −0.115; 95% CI: [−0.206, −0.022]).

DISCUSSION

Broad-extent, fine-grain, spatially-explicit analyses of whole ecosystems are key to illuminating macroecological phenomena such as forest resilience to disturbance (Heffernan et al. 2014). We used a powerful, cloud-based geographic information system and data repository, Google Earth Engine, as a ‘macroscope’ (Beck et al. 2012) to study feedbacks between vegetation structure and wildfire disturbance in yellow pine/mixed-conifer forests of California’s Sierra Nevada mountain range. With this approach, we reveal and quantify general features of this forest system, and gain deeper insights into the mechanisms underlying its function.

High-severity wildfire and ecological resilience

Wildfire severity can be considered a direct correlate of a forest’s resistance – the ease or difficulty with which a disturbance changes the system state (Folke et al. 2004; Walker...
et al. 2004). One relevant state change for assessing ecosystem resistance is the loss of its characteristic native biota (Keith et al. 2013), which could be represented as overstorey tree mortality (e.g. severity) in a forested system. The same fire behaviour in two different forest systems (e.g. old-growth conifer versus young conifer plantation) may have very different abilities to cause overstorey mortality (Keeley 2009), which reflects differences in each forest’s resistance. Resistance is a key component of resilience (Folke et al. 2004; Walker et al. 2004) and, in this framework, one manifestation of forest resilience is high resistance to wildfire, whereby some mechanism leads to lower severity when a fire occurs. Here, we show clear evidence that structural heterogeneity fulfils this mechanistic resistance role in dry coniferous systems (Fig. 5). This study thus provides a particularly extensive, large-scale example of an association between local structural heterogeneity and

Table 1 Comparison of four models described in eqn 2 using different neighbourhood sizes for calculating forest structural variability (standard deviation of NDVI within the neighbourhood), neighbourhood mean NDVI, and topographic roughness (standard deviation of elevation within the neighbourhood). LOO is a measure of a model’s predictive accuracy (with lower values corresponding to more accurate prediction) and is calculated as $−2$ times the expected log pointwise predictive density (elpd) for a new dataset (Vehtari et al. 2017). ΔLOO is the difference between a model’s LOO and the lowest LOO in a set of models (i.e. the model with the best predictive accuracy). The Bayesian $R^2$ is a ‘data-based estimate of the proportion of variance explained for new data (Gelman et al. 2019). Note that Bayesian $R^2$ values are conditional on the model so shouldn’t be compared across models, though they can be informative about a single model at a time.
ecosystem resilience, a phenomenon that has been demonstrated in other systems at smaller scales.

These findings do not imply that resistance to fire is a sole or necessary path to resilience. For instance, high-severity fire is characteristic of other forest systems such as serotinous lodgepole pine forests in Yellowstone National Park, and is not ordinarily expected to hamper forest regeneration (Turner et al. 1997). Our inference that structural variability is a fundamental resilience mechanism in dry coniferous forests is strengthened by its large effect size and our ability to measure the negative feedback phenomenon at relevant spatiotemporal scales: we captured local-scale variability in structure and wildfire severity at broad spatial extents for an extensive set of over 1000 fires across a 34-year time span.

Factors influencing the probability of high-severity wildfire

We found that the strongest influence on the probability of high-severity wildfire was pre-fire NDVI. Greater NDVI corresponds to high canopy cover and vegetation density (Rouse et al. 1973) which translates directly to live fuel loads in the forest canopy and can increase high-severity fire (Parks et al. 2018). Overstorey canopy cover and density also correlate (though weakly) with surface fuel loads (Lydersen et al. 2015; Collins et al. 2016; Cansler et al. 2019), which can play a large role in driving high-severity fire in these forests (Agee 1996). Thus NDVI is likely a strong predictor of fire severity because it is correlated with both surface fuel loads and canopy live fuel density.

We found a strong positive effect of potential annual heat load as well as a strong negative effect of 100-hour fuel moisture, results which corroborates similar studies (Parks et al. 2018). Some work has shown that terrain roughness (Haire & McGarigal 2009; Holden et al. 2009; Dillon et al. 2011; Krawchuk et al. 2016) can be an important predictor of wildfire severity, but we found no effect using our measure of local terrain variability. This may be a function of scale – our measures of topographic roughness were more localised than those of other studies (Holden et al. 2009; Dillon et al. 2011). Haire & McGarigal (2009) also found occasional instances where small differences in topographic roughness had dramatic differences in severity. These sorts of influences on severity would be challenging to detect in our modelling framework, which was designed to estimate an overall influence of topographic roughness on fire severity. Also, topographic roughness could be measured in different ways that highlight different types of heterogeneity (Haralick et al. 1973), which suggests that an effect of topographic roughness on mean wildfire severity will be best-captured by a roughness measure that aligns with the dominant phenomenon driving that effect. Finally, the observed influence of topographic roughness in other studies may have been fully or partially driven by variability in vegetation, which we partition separately in our study.

Critically, we found a strong negative effect of forest structural variability on wildfire severity that was opposite in direction but similar in magnitude to the effect of potential annual heat load. Just as the positive effect of NDVI is likely driven by increased fuel loads, the negative effect of variability in NDVI, is likely driven by discontinuity in surface, ladder, and canopy fuels, which can reduce the probability of initiation and spread of tree-killing crown fires (Wagner 1977; Agee 1996; Graham et al. 2004). This discontinuity can manifest in a number of ways. For instance, neighbouring forest pixels with different tree size distributions may disrupt a crown fire's spread from a low to a high crown or vice versa. Local NDVI variability may also reflect heterogeneous arrangement of vegetation types such as a forested pixel adjacent to a pixel mostly covered by grass. In the grass-dominated area, the relatively low flame heights would likely fail to initiate or sustain active crowning behaviour that would kill overstorey trees in the neighbouring forested area. Finally, forest structural variability may also arise with different land cover types in the local neighbourhood that influence severity, such as when exposed bedrock or a group of boulders acts as fire refugia for vegetation rooted within it (Hylander & Johnson 2010).

Feedback between forest structural variability and wildfire severity

This system-wide inverse relationship between structural variability and wildfire severity closes a feedback that links past and future fire behaviour via forest structure. Frequent wildfire in dry coniferous forests generates variable forest structure (North et al. 2009; Larson & Churchill 2012; Malone et al. 2018), which in turn, as we demonstrate, dampens the severity of future fire. In contrast, exclusion of wildfire homogenises forest structure and increases the probability that a fire will produce large, contiguous patches of overstorey mortality (Stevens et al. 2017; Steel et al. 2018). The proportion and spatial configuration of fire severity in fire-prone forests are key determinants of their long-term persistence (Stevens et al. 2017; Steel et al. 2018). Lower-severity fire or scattered patches of higher-severity fire reduce the risk of conversion to a non-forest vegetation type (Kemp et al. 2016; Stevens-Rumann et al. 2018; Walker et al. 2018), while prospects for forest regeneration are bleaker when high-severity patch sizes are much larger than the natural range of variation for the system (Miller & Safford 2017; Stevens et al. 2017; Stevens-Rumann & Morgan 2019). Thus, the forest-structure-mediated feedback between past and future fire severity underlies the resilience of the Sierra Nevada yellow pine/mixed-conifer system.

Scale of effect of variability in forest structure

We found that the effect of a forest patch’s neighbourhood characteristics on the probability of high-severity fire was strongest at the smallest neighbourhood size that we tested, 90 × 90 m. This suggests that the moderating effect of forest structure variability on fire severity is a very local phenomenon. This corroborates work by Safford et al. (2012), who found that crown fires (high tree-killing potential) were almost always reduced to surface fires (low tree-killing potential) within 70 m of entering a fuel reduction treatment area.

Severity patterns at a landscape scale (e.g. for a whole fire) may represent cross-scale emergences of the local influence of
forest structure variability on fire effects (Peters et al. 2004; Rose et al. 2017). For instance, forest management actions (e.g. prescribed fire, use of wildfire under mild conditions) that reduce fuel loads and increase structural variability can be effective at reducing fire severity across broader spatial extents than the direct footprints of those actions (Graham et al. 2004; Stephens et al. 2009; Tubbs et al. 2019). Some work suggests that this sort of cross-scale emergence may depend on even broader-scale effects of fire weather, with small-scale variability failing to influence fire behaviour under extreme conditions (Peters et al. 2004; Lydersen et al. 2014), though we did not detect such an interaction between our metric of burning conditions (100-hour fuel moisture) and forest structure variability.

Correlation between covariates and interactions

Unexpectedly, we found a strong interaction between the pre-fire NDVI at a pixel and its neighbourhood mean NDVI on the probability of high-severity fire. These two variables are strongly correlated (Spearman’s $\rho = 0.97$), so the general effect of this interaction is to dampen the dominating effect of pre-fire NDVI. Thus, though the marginal effect of pre-fire NDVI on the probability of high-severity fire is still positive and large, its real-world effect might be more comparable to other modelled covariates when including the negative main effect of neighbourhood mean NDVI, the negative interaction effect of pre-fire NDVI and neighbourhood mean NDVI, and their tendency to covary (compare the effect of pre-fire NDVI under the common scenario of pre-fire NDVI and neighbourhood mean NDVI increasing or decreasing together: $\beta_{\text{pre-fire NDVI}} + \beta_{\text{nbhd_mean_NDVI}} + \beta_{\text{nbhd_mean_NDVI}*\text{pre-fire NDVI}} = 0.352$, to the effect of 100-h fuel moisture, which becomes the effect with the greatest magnitude: $\beta_{\text{fuel moisture}} = -0.576$).

In the few cases when pre-fire NDVI and the neighbourhood mean NDVI contrast, there is an overall effect of increasing the probability of high-severity fire. When pre-fire NDVI at the central pixel is high and the neighbourhood NDVI is low (e.g. an isolated vegetation patch; Figure S2), the probability of high-severity fire is expected to dramatically increase. When pre-fire NDVI at the central pixel is low and the neighbourhood NDVI is high (e.g. a hole in the forest; Figure S2), the probability of high-severity fire at that central pixel is still expected to be fairly high even though vegetation is sparse there. In these forest NDVI datasets, when these variables do decouple, they tend to do so in the ‘hole in the forest’ case and lead to a greater probability of high-severity fire at the central pixel despite its low NDVI. This can perhaps be explained if the consistently high vegetation density in a local neighbourhood – itself more likely to burn at high-severity – exerts a contagious effect on the central pixel, raising its probability of burning at high-severity regardless of how much fuel might be there to burn.

CONCLUSIONS

Theory and empirical work suggest a general link between forest structural heterogeneity and resilience. Here we find strong evidence with a large-scale study that, across large areas of forest, variable forest structure generally makes yellow pine/mixed-conifer forest in the Sierra Nevada more resistant to inevitable wildfire disturbance. It has been well-documented that frequent, low-severity wildfire maintains forest structural variability. Here we demonstrate a system-wide reciprocal effect suggesting that greater local-scale variability of vegetation structure makes fire-prone, dry forests more resilient to wildfire and may increase the probability of their long-term persistence.

ACKNOWLEDGEMENTS

We thank Connie Millar, Derek Young and Meagan Oldfather for valuable comments about this work and we also thank the community of Google Earth Engine developers for prompt and helpful insights about the platform. We thank four anonymous reviewers for their helpful comments on the manuscript. Funding for this work was provided by NSF Graduate Research Fellowship Grant #DGE-1321845 Amend. 3 as well as by Earth Lab through CU Boulder’s Grand Challenge Initiative and the Cooperative Institute for Research in Environmental Sciences (CIRES) at CU Boulder (to MJK).

AUTHORSHIP

MJK, CMW, SEF and AML conceived the study. MJK, SEF and CMW wrote the Earth Engine code. MJK performed the analysis, with input from all authors. MJK wrote the first draft of the manuscript. All authors contributed substantially to editing and revisions.

DATA ACCESSIBILITY STATEMENT

The data and analysis code supporting the results are archived on the Open Science Framework at www.doi.org/10.17605/OSF.IO/27NSR.
