Control of Rhizoctonia Foliar Blight in Forest Seedling Nurseries: A 3-Year Study

Tom E Starkey, Scott A Enebak, Ken McQuage, and Kevin Barfield

Introduction

The availability of fungicides to control specific forest seedling nursery diseases is either nonexistent, limited, or faces possible loss of US label registration. Of the many insects and diseases that occur in forest-tree nurseries, three fungal pathogens stand out as problematic in southern US nurseries. These diseases include fusiform rust, pitch canker, and Rhizoctonia foliar blight. Nearly all nurseries in the southern US routinely apply fungicides to prevent fusiform rust on seedlings. Rhizoctonia foliar blight is the second most frequently occurring disease in this region.

Longleaf (Pinus palustris) and loblolly (P. taeda) pines are particularly susceptible to Rhizoctonia foliar blight (English and others 1986, Runion and Kelley 1993). The disease is caused by a species of Rhizoctonia spp. or binculeate forms of sexual states belonging to the genera Thanatephorus or Ceratobasidium. Rhizoctonia foliar blight can cause significant pine mortality in nursery beds and typically occurs in late July when the seedling canopy closure. Disease spread within test areas was not correlated with the prevailing winds indicating the inoculum source was within the test area. Forest seedling nurseries should change their initial fungicide application from canopy closure to 1-2 fungicide applications prior to canopy closure to reduce inoculum and disease pressure later in the growing season. Proline® is currently labeled for use in forest seedling nurseries.
blight generally is not distributed uniformly throughout a nursery and is limited to foci within nursery beds. The disease is also more severe in second or third year crops post soil fumigation. While there are fungicides registered for *Rhizoctonia* foliar blight, they are not always efficacious (Carey and McQuage 2004) with azoxystrobin being the most commonly used fungicide (McQuage, 2009 personal communication). In most nurseries in the southern region, fungicide applications begin in mid-July when seedling canopy closure occurs.

In an attempt to find alternatives for the control nursery diseases, trials examining numerous fungicides by have been conducted by the Southern Forest Nursery Management Cooperative since 2004. In 2008, Proline® 480 SC (41% prothioconazole, Bayer CropScience) (Table 1), was examined as it had a broad spectrum systemic control of ascomycetes, basidiomycetes, and deuteromycetes on numerous field food crops. Prothioconazole belongs to the new chemical class of triazolinethiones (Mauler-Machnik and others 2002) and inhibits the demethylation process at position 14 of lanosterol or 24-methylene dihydrolanosterol, which are precursors of sterols in fungi. Prothioconazole efficiently stops many steps of the fungal infection chain like appressorium and haustoria formation, mycelial growth as well as spore formation. When these research studies were initiated, Proline® was only registered in the US for food crops including peanuts, barley, wheat, sugar beets, beans, soybeans, and rapeseed. Beginning in 2008, data collected from the studies reported in this paper and other studies by the Southern Forest Nursery Management Cooperative were used to obtain a full-use label in December 2011 for disease control in forest-tree nurseries in the southern US.

The creation and expansion of these programs had a profound effect on state nurseries. An examination of seedling production shows this effect. In 1939, the 17 state nurseries that were operating produced 77,205,000 seedlings, but by 2010, the 16 state nurseries still produced 118,299,000 seedlings. This dramatic increase was the result of increased mechanization, improved seed quality, and an improved understanding of seedling growth and development. These improvements made it possible for production to reach 2.3 billion tree seedlings in one year at the peak of the CRP. At the same time, the numbers of state nurseries were also at their all-time high of 20 non-amended PDA plates used as a control. A #4 cork-borer (0.31 in; 8 mm) plug of *Rhizoctonia solani* taken from a 12-day old culture was placed at the center of each plate. The radial fungal growth was measured over a period of 7 days and recorded.

**Methods**

**Rhizoctonia Foliar Blight Laboratory Trials**

Fungal growth studies were conducted in the laboratory to determine if *Rhizoctonia solani* was able to grow on agar media amended with Proline® at 1x, 0.25x and 0.0625x the label rate of 5 fl oz/ac (1 fl oz/ac = 73.1 ml/hectare). Potato Dextrose Agar (Difco® PDA) was amended with Proline® after autoclaving and just prior to pouring the plates. There were 20 PDA plates of each fungicide concentration and 20 non-amended PDA plates used as a control. A #4 cork-borer (0.31 in; 8 mm) plug of *Rhizoctonia solani* taken from a 12-day old culture was placed at the center of each plate. The radial fungal growth was measured over a period of 7 days and recorded.

**Results and Discussion**

**Rhizoctonia Foliar Blight Laboratory Trials**

Agar media amended with Proline® resulted in 100% control of *Rhizoctonia solani* as fungal growth did not occur on any of the Proline®-amended PDA plates for any concentration used for the 7 day experiment (Figure 2). This control of fungal growth with all concentrations of Proline® cannot be directly extrapolated to field use, but it does indicate that rates lower than recommended label rates may be effective.
Control of *Rhizoctonia* Foliar Blight in Forest Seedling Nurseries: A 3-Year Study

Starkey, Enebak, McQuage, and Barfield

**Rhizoctonia Foliar Blight Field Trials**

In 2008, when Proline® and Abound® were sprayed at label rates at two week intervals, disease incidence, severity and number of seedling mortality in Proline® treated plots was significantly less than in the Abound® and non-treated control plots (Table 2). The potential monetary loss due to *Rhizoctonia* foliar blight was $967, $209 and <$1, per acre for non-treated, azoxystrobin, and prothioconazole, respectively. The potential monetary loss in Table 2 reflects the seedling loss in the test plot, not the whole nursery as *Rhizoctonia* foliar blight tends to occur in isolated foci in susceptible seedlots. There were no significant differences in either seedling quality or root morphology between the two fungicides tested, although the control plots had numerically fewer seedlings.

Seedlings sprayed with Proline® exhibited a “greening-up” effect that remained until the final application of Proline®. This “greening-up” effect had never been observed with any other fungicides at this nursery previously. Figures 3, 4 and 5 represent the control, Abound® and Proline® sprayed plots, respectively. The greening up effect has been observed on other crops treated with Proline® and it is reported that triazole fungicides can act to delay senescence by the generation of H$_2$O$_2$ as an intermediate metabolite (Audenaert and others 2010).

When the interval between fungicide sprays was increased from 2 to 3 weeks, Abound® had a disease incidence of 8.6% compared to <1% for the Proline® (Table 2). When comparing the two studies, the disease intensity doubled for the Abound® applications and the potential loss per acre increased over 300% when applied every 2 weeks versus...
between Proline® sprays using suggested label rates is not as critical as specified on the label. This study suggests that the time interval between plots sprayed at 3 fl oz/ac was lost at the 3 fl oz/ac than 5 fl oz/ac following canopy closure (Figure 6). After canopy closure the temperature and moisture conditions, along with seedling-to-seedling contact facilitated the aerial spread of Rhizoctonia foliar blight. In each year the appearance of Rhizoctonia foliar blight did not occur until early September which is 3-4 weeks later than previously growing seasons. When comparing Proline® sprayed at 5 and 3 fl oz/ac, more seedlings were lost at the 3 fl oz/ac than at 5 fl oz/ac following canopy closure (Figure 6). After canopy closure the temperature and moisture conditions, along with seedling-to-seedling contact facilitated the aerial spread of Rhizoctonia foliar blight.

The appearance of Rhizoctonia foliar blight within the field plots in 2008 and 2009 was limited to the unsprayed control plots. In 2011, it is possible that the aerial spread on Proline® foliar blight was limited to the control plots following canopy closure (Figure 6). After canopy closure the temperature and moisture conditions, along with seedling-to-seedling contact facilitated the aerial spread of Rhizoctonia foliar blight.

The appearance of Rhizoctonia foliar blight within the field plots in 2008 and 2009 was limited to the unsprayed control plot followed by plots treated with Abound®. There was little movement from either the control or Abound® plots into the Proline® plots. In 2011, Rhizoctonia foliar blight was limited to the control plots followed by the Proline® plots sprayed at 3 fl oz/ac. In each year the study-plot location was in a different area of the nursery. There was no correlation of disease spread and the prevailing wind direction during any year indicating that the inoculum within the field was the primary source for plot to plot and row to row spread. The shaded boxes are the period when the temperature and free moisture fell within the bounds favorable for Rhizoctonia reported above. The earliest occurrence of Rhizoctonia occurred in 2008 and the latest was in 2011. In 2011, it is possible that the aerial spread on Rhizoctonia was inhibited due to the high temperatures that summer. The temperatures in 2011 were the 3rd hottest temperatures on record in 117 years. Temperatures exceeded 90°F 69% of the days from canopy closure to the first appearance of Rhizoctonia in the nursery. The shaded boxes are the period when the temperature and free moisture fell within the bounds favorable for Rhizoctonia reported above. The earliest occurrence of Rhizoctonia occurred in 2008 and the latest was in 2011. In 2011, it is possible that the aerial spread on Rhizoctonia was inhibited due to the high temperatures that summer. The temperatures in 2011 were the 3rd hottest temperatures on record in 117 years. Temperatures exceeded 90°F 69% of the days from canopy closure to the first appearance of Rhizoctonia foliar blight.

In December 2011, Proline® was approved by EPA for use in forest-tree nurseries. Proline® can be used to control diseases on nursery seed and seedlings of shortleaf, loblolly, slash and longleaf pines in addition to other pines, conifers and hardwoods. Before using any new pesticide, it is always a safe practice to apply it to a test area before larger areas in the nursery. The Proline® label can be viewed at http://www.cdms.net/LDat/ld89K000.pdf.
Management Implications

Laboratory studies have shown Proline® is capable of controlling fungi in vitro at rates much lower than the label rate of 5 fl oz/ac. In field studies, Proline® effectively controlled the spread of Rhizoctonia using 5 fl oz/ac which is within the range of 2.5 – 5.7 fl oz/ac for registered crops. Proline® provided significantly better control than Abound® when applied at a spray interval of every 2 or 3 weeks. Increasing spray intervals with fungicides other than Proline® may not be feasible in nurseries prone to Rhizoctonia foliar blight.

Figure 7. 2008 environmental data showing temperature, free moisture, date first Rhizoctonia foliar blight observed (star), and period in which environmental parameters favored fungal growth (shaded boxes).

Figure 8. 2009 environmental data showing temperature, free moisture, date first Rhizoctonia foliar blight observed (star), and period in which environmental parameters favored fungal growth (shaded boxes).
The current practice of initiating fungicide applications for the control of Rhizoctonia foliar blight at canopy closure needs to be changed. Nurseries should start applying 1-2 fungicide applications before canopy closure when it is easier to apply fungicides to the lower stem and needles of the seedling. This will help to reduce the initial amount of inoculum found within the nursery beds and decrease disease pressure later in the growing season. In soybeans, 60% of the primary infection of Rhizoctonia foliar blight occurred before canopy closure (Yang and others 1990).

Mulching may also help prevent initial infection within a nursery bed. In dry beans, (Phaseolus vulgaris L.), mulching was highly effective for the control of Rhizoctonia web blight (Galindo and others 1983). The mulched layer acted as a physical barrier to prevent or reduce the splashing of the inoculum up onto the bean tissue.

The aerial spread of the fungus depends upon free moisture in the canopy. Therefore, in nurseries where Rhizoctonia is a problem, irrigating early in the day so as to allow the foliar to dry before nightfall will reduce the available number of hours of free moisture. Rhizoctonia foliar blight overwinters on seedling debris in the field. Use caution when sowing susceptible families on 2nd or 3rd year land following fumigation.
